NEW YORK, NEW YORK 10112

TO ALL WHOM IT MAY CONCERN:

Be it known that WE, ARNAUD DUFOURNIER and FRANÇOIS HOTTEBART, citizens of France, whose post office addresses are 13, Rue Cuvier, F-63100 Clermont-Ferrand, France; and 32, Chemin de la Pauze, F-63130 Royat, France, respectively, have invented an improvement in

SAFETY INSERT GENERATING A TRANSVERSE
VIBRATING SIGNAL AND DEVICE FOR SENSING
THE TIRE BEARING ON THE INSERT

of which the following is a

SPECIFICATION

BACKGROUND OF THE INVENTION

This is a continuation of PCT EP 98/02251, filed April 17, 1998.

The invention concerns the use of tires equipped with a safety insert and, in particular, detection of the bearing of a tire on the safety insert. It proposes an insert which warns the driver as soon as the tire is bearing on it after a flat or in case of
5 substantial pressure loss, as well as a device for sensing the tire bearing on the insert, which can be combined with the insert proposed.

The function of these safety inserts, which are generally mounted on the rim inside the tire, is to ^{bear}~~absorb~~ the load in case of failure of the tire.

09/14/99
AD
5 Bearing of the tire on the safety insert is accompanied by a more or less marked deterioration of its performances, which cannot fail to be perceptible to the driver through the behavior of the vehicle and the discomfort of the passenger. Furthermore, the operating lifetime of these inserts is limited. It is therefore essential, for the driver's safety, for the driver to be warned as soon as a tire is bearing on its safety insert, so that the driver can follow the manufacturer's instructions.

10 Several safety inserts incorporating means for so warning the driver have previously been proposed.

U.S. Patent 4,262,724 discloses a safety insert intended to be mounted in an assembly comprising a tire and a rim and radially on the outside of the rim. This insert has a radially outer surface which defines a radial bearing for the crown of the tire, when the tire is deflated, as well as means for generating vibrating warning signals on running
15 flat. These means can be a variation of the rolling radius under bearing of the insert between a minimum radius and a maximum radius in order to create a rolling vibration or one or more ^{bumps}~~bosses~~. All the vibrating warning signals generated by these means are oriented in the plane of the tire and rim assembly and, more specifically, in a roughly vertical direction.

20 These solutions pose several problems. In addition to marked discomfort for passengers of the vehicle, they can markedly degrade the performance of the tire and rim assembly concerned, particularly on acceleration and braking. Thus, all one can do is

avoid instantaneous stoppage of the vehicle in case of failure of the tire. On the other hand, when it is desired to use the vehicle, even at limited speed, over long distances, the warning transmitted by the insert has to be compatible with driving safety, not detrimental to the mechanics, while remaining perfectly noticeable to the driver either directly or through a suitable detection device.

Patent application WO 94/03338 also proposes a device for the detection of the bearing of a tire on a safety insert. This device comprises a wheel accelerometer, placed on one of the wheel suspension elements and measuring vertical accelerations. The accelerometers are connected to a central processing unit. The analysis is based on detection of the appearance of a resonance mode characteristic of the run-flat condition.

SUMMARY OF THE INVENTION

The object of the invention is a safety insert which warns the driver, either directly or indirectly, upon bearing of the tire over a very wide range of speeds of the vehicle, while remaining tolerable to the driver and the mechanics within the speed limits.

The invention also concerns a device for detection of the bearing of a tire on its safety insert, which can, notably, cooperate with the safety insert according to the invention.

"Vehicle" is understood below to be a self-contained rolling unit, passenger car, truck, tractor-trailer, motorcycle, etc.

"Rib" refers to an element situated on the radially outer surface of a safety insert, of elongated shape, of roughly circumferential orientation and the radial height of

which is less than or equal to the axial width: the ribs are "straight" when their axial section is rectangular and "inclined" when their axial section is in the shape of a parallelogram.

"Incision"

"Strip" describes a similar element whose radial height is greater than the

axial width.

The safety insert according to the invention, intended to be mounted in an assembly comprising a tire and a rim of a vehicle and radially on the outside of the rim, presents a radially outer surface which defines a radial bearing for the crown of the tire when it is deflated and means for generating vibrating warning signals on a run-flat condition. The said insert is characterized in that said means generate signals oriented parallel to the axis of rotation of the tire and rim assembly.

Said insert has two major advantages: the vibrating signals generated in the transverse direction are much more easily transmitted to the chassis and to the driver than similar vertically oriented signals. This is due to the excellent filtering carried out by the vehicle suspensions in the vertical direction in order to preserve the comfort of the passengers of the vehicle, while any transmission of stresses in the transverse direction is almost direct, with few filtering elements. On the other hand, those transverse vibrating signals degrade the performance of the tire and rim assembly in a straight line markedly less than those vertically oriented.

In a first embodiment of the invention, the bearing surface of the insert presents a variation of transverse direction according to its azimuth.

In a second embodiment, the bearing surface of the insert presents straight ribs, the circumferential orientation of which varies with their azimuth.

And in a third embodiment, the bearing surface of the insert presents elements generating a transverse stress on their radial compression.

5 This embodiment is particularly flexible. It is, in fact, possible to use inclined ribs or ^{incisions} ~~strips~~ relative to a longitudinal plane in variable manner according to their azimuth.

In a preferred variant, the safety insert according to the invention has a bearing surface with at least two axially adjacent zones, the zone intended to be placed
10 outward from the vehicle not containing means for generating signals oriented parallel to the axis of rotation of the tire and rim assembly.

The latter solution has the advantage of preserving excellent turn performance of the tire and rim assembly upon running on a safety insert. In fact, on a turn, the tires placed outward from the turn are more loaded and usually take a marked
15 counter-camber angle. Under such conditions, it is the "inactive" bearing zone (that is, not containing means for generating signals oriented parallel to the axis of rotation of the tire and rim assembly) which supports the bulk of the tire load without generating specific transverse vibrating signals. On the other hand, on a straight run, the tires have a much smaller camber angle and, the bearing zone containing means for generating
20 transverse vibrating signals, the "active" zone is then stressed.

The shape of the signal generated by the safety insert is also very important. The safety insert according to the invention preferably comprises a bearing

surface with an active signal-generating zone, so that said signals present a maximum preceded and followed by a minimum in the opposite direction.

The active zone advantageously ranges between $\frac{1}{4}$ and $\frac{1}{2}$ the circumference of said insert and the absolute value of the minima of the signal generated ranges between $\frac{1}{4}$ and $\frac{3}{4}$ the absolute value of the maximum.

Such generated signals have the advantage of giving a spectrum of vibrations transmitted to the chassis of the vehicle on a run-flat condition in a well defined frequency band which favors precise and reliable detection.

The invention also concerns a first device for detection of the bearing of a tire of a vehicle, equipped with a plurality of tire, rim and safety insert assemblies mounted between the rim and the radially inner face of the tire tread, on the corresponding safety insert, each assembly being capable of triggering the emission of a vibrating signal, when the tire comes in contact with the insert after a pressure loss in the tire. Said detection device comprises means of detection and treatment of said vibrating signal, containing a single sensor capable of being mounted on the vehicle and sensitive to the signals emitted by each of the assemblies, when the corresponding tire comes in contact with the respective insert, and an indicator capable of signaling to the occupant of the vehicle a run-flat condition in response to a signal picked up by said sensor.

The characteristic vibrating signal is preferably maintained by the run-flat condition and can be emitted by a pressure-sensitive generator. Such a generator placed in the insert or on its surface is sensitive to any stress associated with the bearing of the tire tread on the insert and emits a signal, acoustic, for example, when that stress exceeds

a given threshold. The acoustic signal can be easily picked up by a single receiver placed in the passenger space of the vehicle, connected to an indicator capable of warning the occupant of the vehicle of the run-flat condition.

The invention also concerns a second device for detection of bearing of a
5 tire of a vehicle, equipped with a plurality of tire, rim and safety insert assemblies mounted between the rim and the radially inner face of the tire tread, on the corresponding safety insert, each assembly being capable of transmitting a characteristic vibration to the chassis of the vehicle in response to the bearing of one of the tires on the corresponding safety insert as a result of a pressure loss in the tire. This device
10 comprises:

- means of detection and treatment of such predetermined characteristic mechanical vibration of the chassis of the vehicle;
and
- means of transmission of an alarm.

15 This device presents the feature, by comparison with known devices, of making an analysis of the vibrations of the chassis of the vehicle instead of the suspension members.

As in the insert previously described, said device can preferably use direct paths of transmission of vibrations between the wheels and the chassis, in addition to
20 vertical directions. Consequently, said device can be much more selective and sensitive than the existing devices and may have only one sensor rigidly connected to one of the parts of the chassis.

The device according to the invention is particularly well-suited to detection of bearing of a tire on a safety insert according to the invention, but it can also be used with any other insert, with or without vibrating means for alerting the driver to the bearing problem. In such case, it may be necessary to use two or more sensors
5 measuring accelerations instead of only one. Each sensor is then preferably connected to one of the axles of the vehicle.

The means of treating vibrations of the chassis calculate a first characteristic magnitude in at least one given frequency band, they calculate a criterion C corresponding to a given combination of the preceding first characteristic magnitude or
10 magnitudes, they compare that criterion C to a given threshold and they trip an alarm when the result of the comparison follows a given ratio.

Preferably, for each of the axles of the vehicle, the treatment means calculate a first characteristic magnitude in at least a first frequency band specific to the axle of the vehicle and calculate a criterion C corresponding to a weighted value of these
15 first characteristic magnitudes.

The means of treating the vibrations of the chassis can also calculate, in addition, a second characteristic magnitude in a given second frequency band, so that, in said second band, said vibrations are appreciably independent of the bearing of the tire on its safety insert and deduce therefrom a criterion C corresponding to a value normed by
20 that second characteristic magnitude of the first characteristic magnitudes, weighted or not.

- 9-

- Figure 3 shows, in meridian section, a second embodiment;
- Figure 4 shows, in meridian section, a third embodiment;
- Figure 5 shows, in cross section, a safety insert with two axially adjacent zones;
- 5 - Figure 6 shows schematically a preferential shape of signals generated by the insert on rolling;
- Figure 7 is a schematic diagram of the detection device according to the invention;
- Figure 8 presents two spectra of measurement of appreciably horizontal accelerations according to frequency with and without bearing registered on an ordinary road;
- 10 - Figure 9 illustrates an example of evolution with time upon rolling with or without bearing of the resultant magnitude calculated by the microcontroller of the device;
- 15 - Figures 10a and 10b show, in meridian section, two variant tire and rim assemblies equipped with a safety insert.

DESCRIPTION OF PREFERRED EMBODIMENTS

Figure 1 shows a wheel rim 1 equipped with an annular safety insert 2 resting on the bearing 6 of the rim 1. The particular geometry of said wheel rim 1 is described in French patent application No. 2,713,558. It provides two bead seats of different diameters and is particularly well suited for the easy placement of that safety

20

insert 2. This assembly makes rolling possible in spite of a large pressure drop in the tire

3. In case of such rolling, the inside of the deformed tire rubs on the outer surface of the insert, producing heating which limits the available radius of action; it is therefore important for the driver to be informed as soon as a tire rests on its inset 2.

5 For this purpose, a safety insert according to the invention is used as insert, containing means for generating transverse vibrating warning signals.

A first embodiment of such an insert is shown in Figure 2. This insert 9 has a bearing surface 10 which is axially shifted according to its azimuth. Consequently, upon a run-flat condition of said surface 10 against that of the crown of the tire, the tire, rim and insert assembly will produce on each turn of the wheel a lateral thrust oscillation that the driver or a detection device will perceive.

Figure 3 shows another embodiment. The bearing surface 13 of the insert 12 is formed by ^{incisions} strips 14 inclined relative to a transverse plane of the insert and the inclination of which varies with their azimuth. In the example shown, the inclination is diametrically opposite and the course of the inclination is appreciably sinusoidal. These ^{incisions} strips therefore produce, on ^{loading} ~~crushing~~, transverse stresses of the same frequency as the turn of the wheel, again easily perceptible to the driver of the vehicle, whether directly or not.

It is also possible to use ribs or preferably relatively wide ribs arranged adjacent to ^{incisions} strips of similar or greater radial height. In the latter case, it is advantageous to so design the rigidity and geometry of said ^{incisions} ribs and strips that the radius of rolling of the insert remains constant on a run-flat condition.

Figure 4 shows a safety insert 15 containing two axially adjacent zones A and B. Zone B, arranged on the side intended to be placed outward from the vehicle, does not contain means for generating signals oriented parallel to the axis of rotation of the tire and rim assembly. Said zone is thus inactive when zone A, arranged toward the vehicle, contains ^{incisions} strips inclined to generate transverse vibrating signals. Said insert 15 makes it possible to maintain excellent turn performance, for it is then the roughly cylindrical zone B which supports most of the load of bearing of the crown of the tire, by reason of the wide angle of counter-camber taken by the latter. In a straight line, the operation of the insert 15 is similar to that of Figures 2 and 3.

Such an insert can also advantageously have a slight conical zone B with its minimum diameter on the outer side of the insert, in order to fit well the counter-camber angle taken by the tire and wheel on turning. There can also be an insert containing two adjacent cylindrical or conical zones on the outside of a central active zone.

Figure 5 shows an insert 16 containing, in addition to ^{incisions} slats of inclination varying with the azimuth, two radial ^{bumps} bosses 17 and 18 created by giving the ^{incisions} slat a height varying with the azimuth, which result in a vertical vibratory excitation. The circle L corresponds to the outside of the insert bearing surface and the oval M corresponds to the casing at the base of the ^{incisions} slats. The ^{incisions} slats in the present example thus have zero ^{height} thickness at the two crowns of ^{bumps} bosses 17 and 18. It has, in fact, been observed that such an insert 16, coupling generations of transverse and vertical vibrations, appreciably increases the total energy transmitted in the vehicle.

6a

Figure 6 shows a preferred shape of the signal generated by a safety insert

according to the invention. Said signal differs from zero only within a zone limited to approximately $\frac{1}{3}$ the circumference of the insert. It comprises a first minimum F_{Ymin} followed by a maximum F_{Ymax} of opposite direction and followed, finally, by a second minimum. The two minima can have the same amplitude ranging between $\frac{1}{5}$ and $\frac{1}{2}$ of F_{Ymax} .

The safety inserts previously described can easily generate signals similar to those of Figure 6. It is sufficient for the means used to generate the Y signals to vary similarly. In the case of insert 9, the lateral position of the bearing surface 10 can follow a course corresponding to that of a or b of Figure 6. By reason of the weighting due to the finite length of the area of contact between the tire and the bearing surface of the insert, a variation similar to that of b in Figure 6 will result in a course of the signal generated close to the shape of curve a. In the case of insert 12 of Figure 3, it is the orientation of the ribs or ^{incisions} strips which must follow a course corresponding to curves a or b in Figure 6.

In the usual manner, in order to limit heating of the insert and tire on run-flat condition, a lubricant is introduced in the inner cavity of the tire and, in particular, on the bearing surface of the insert. To improve adherence between the bearing surface of the insert and the crown of the tire, it is advantageous to arrange on the bearing surface ^{incisions} strips of roughly circumferential orientation, which will play the same role as the ^{incisions} strips of the tire sculptures in order to remove water in the area of contact between the tire and the road.

The safety inserts according to the invention can generate signals of great enough intensity to be perceived by the driver of a vehicle. However, to preserve the comfort of the passengers of the vehicle, it is also possible to use these inserts with a bearing detector which will now be described.

5 Figure 7 schematically presents the detector according to the invention, intended to be used with a two-axle passenger car, for example, a Renault Twingo. Said device 20 includes a sensor 21; a series of bandpass filters 22, 23, 24; three analog
10 extractors 25, 26, 27 of the rms value of the signals; a microcontroller 28 and an indicator 29. The assembly is placed in a single box designed to be rigidly connected to one of the parts of the chassis of the vehicle. The sensor 21 is preferably a unidirectional
15 accelerometer so arranged in the vehicle that it measures the accelerations in a plane embracing the longitudinal and transverse axes of the vehicle. The signals are then filtered by a series of bandpass filters placed in parallel. Filter 22 eliminates the signals
20 outside a band A adapted to the rear axle of the vehicle, in the order of 20 to 50 Hz. Filter 23 eliminates the signals outside a band B adapted to the front axle of the vehicle,
25 in the order of 50 to 80 Hz and filter 24 lets pass the signals lying in a band E, in which the signals are appreciably independent of the bearing of a tire on its safety insert, in the
30 order of 100 to 200 Hz or preferably of 100 to 160 Hz. These three frequency bands can, notably, vary with the type of safety insert used as well as with the vehicle chosen.

35 Extractors 25, 26 and 27 obtain rms values of the signals transmitted respectively by bandpass filters 22, 23 and 24. The microcontroller 28 digitizes the
40 signals in the digital analog converter (A/N) 30. Element 31 of the microcontroller 28

calculates a criterion C; it can notably produce a weighted total of the rms values of the signals of bands A and B and norm that total by the rms value of the signals of band E.

The vibrational energy lying in band E depends on the type of road on which the vehicle runs. The normalization obtained appreciably improves the sensitivity of the detector by reducing the number of false alarms. Said band E can also lie in a very low frequency band, in the order of 3 to 7 Hz, for example.

Criterion C is then compared to a programmable given threshold 33 in the comparator 32 and an alarm is set off by means of the indicator 29 when C is higher than the threshold.

Figure 9 presents the course of criterion C when the four tires of the Renault Twingo are correctly inflated (zone A) and when one of those tires is deflated, which results in the bearing of that tire on its safety insert (zone B). Curve 1 shows the rough course of C and curve 2 shows the result after comparison with the threshold. Said result is zero when C is below the threshold and is 1 when C is above the threshold.

The indicator transmits an alarm to the driver when the result of comparison is 1. Said indicator can be accompanied by a buzzer.

In the case of a heavy-load vehicle, as many frequency bands can be adopted as there are axles in the vehicle, tractor or trailer. There are, of course, also as many sensors as there are vehicles.

When the speed of the vehicle diminishes and approaches zero, the vibrational energy of the different signals diminishes and becomes more and more

sensitive to local disturbances. Consequently, tripping of the alarms can be stopped when the speed of the vehicle is below a given threshold, for example, 7 km/h.

Figure 8 shows an example of a spectrum of vibrations measured by the sensor 21 upon rolling with the Renault Twingo. A first curve corresponds to the case in which the four tires are correctly inflated. A peak is usually observed at the low frequencies, toward 9 Hz; that peak corresponds to the first harmonic of the turn of the wheel.

A second curve corresponds to the case in which a tire on the front axle is deflated and bearing on its safety insert. Said curve presents a strong spectral response between 50 and 75 Hz with peaks linked to the different harmonics of the turn of the wheel. In this case, the 50-80 Hz band B has been chosen as characteristic frequency band of that front axle.

The third curve illustrates the case in which one of the tires of the rear axle of the Renault Twingo is bearing on its safety insert. Two notable peaks are observed toward 20 and 40 Hz. The 20-50 Hz band A is then chosen as characteristic band of the rear axle.

It is also observed in Figure 8 that, in frequencies below 7 Hz, or between 100 and 200 Hz, there is practically no noticeable change in the curves whether or not running flat. Consequently, in order to take into account the vibrational energy due to the type of road on which the vehicle runs, the measurements are normed in the preceding characteristic frequency bands by measurement of the rms value in a band E such as 100-160 Hz or 3-7 Hz. This makes it possible to rely on the quality of the bearing detection.

When the speed of the vehicle diminishes, so that the first harmonic of the turn of the wheel becomes around 7 Hz, in order to avoid disturbances, the transmission of alarms is inhibited.

To have a single criterion of bearing detection and taking into account the notable energy differences between the measurements upon bearing of a front or rear tire on its insert, the measurements can be weighted in order to obtain a characteristic magnitude roughly of the same value, regardless of the axle of the tire bearing on its insert. This is what is done for the curve presented in Figure 9.

Curves 8 and 9 are obtained with a safety insert generating a transverse signal over one-third the circumference of the insert and varying between zero and F_{Ymax} . This generated signal has a broader spectrum than that of Figure 6. The detector used has a single unidirectional sensor rigidly connected to the chassis of the vehicle placed with a transverse orientation.

The signal shape presented in Figure 6 has the advantage of well delimiting in frequency the signals transmitted to the chassis of the vehicle and of concentrating those signals in mainly a single frequency band. Said band is defined to embrace, whatever the speed of the vehicle beyond a few kilometers per hour, the characteristic frequency bands of each of the axles of the vehicle. This makes it possible to rely on the quality of detection and to limit false alarms. This also makes it possible to use the energy transmitted to best advantage without degrading the comfort of the vehicle. The F_{Ymax} values of those signals can thus be reduced.

According to another embodiment, the means of treatment:

- determine the frequency of rotation of the tires of the vehicle;
- calculate the frequencies of n first harmonics of the frequency of rotation of the tires (turn of the wheel);
- 5 - calculate the vibrational energies of the n narrow frequency bands centered on the n first harmonics;
- figure, if necessary, the total of the three maximum energies in order to obtain a criterion C;
- compare that criterion C to a function threshold of speed and
- 10 unevennesses of the road; and
- trip an alarm if C is higher than that threshold.

The speed information can be obtained from the tachometer of the vehicle; it can also be deduced from the signals registered by determining the frequency position of the first peak (see Figure 8).

15 "Narrow band" of frequency is understood to be a band of width below 5 Hz.

As can be seen on the curves of Figure 8, the frequencies corresponding to the harmonics of the first peak (turn of the wheel) are also spectrum peaks.

Consequently, analyzing the harmonics of the turn of the wheel makes it possible to

20 improve very appreciably the detection of bearing of a tire on its safety insert.

To facilitate calculations, they can be limited to a few harmonics, from 5 to 11, for example, from harmonic 2 to harmonic 6 or 12, depending on the vehicles. The

corresponding frequencies, for a wide range of speeds of the vehicle, are found in the frequency band where the vibrations of the insert can be transmitted to the chassis of the vehicle by the different suspension elements. Said band usually lies between 10 and 200 Hz.

5 As it is always possible for one or more peaks to be disturbed by other sources, such as vibrations of the engine, it is useful to analyze these harmonics to calculate the vibrational energies of the narrow bands centered on them and to total, for example, the three maximum energy bands in order to calculate criterion C.

10 As previously, it is useful to determine the vibrational energy in at least one frequency band, in which the spectrum measured is appreciably independent of bearing, in order to be able to estimate what might be due to the unevennesses of the road traveled. In this method of analysis, said second band should not contain the harmonics of the turn of the wheel.

15 Criterion C is a function of speed of the vehicle; it can be compared to a function threshold of speed and the vibrational energy level due to the road and, as previously, trip an alarm when that threshold is crossed.

20 To avoid false alarms, provision is made for two tests of nontripping of the alarm. The first is linked to the speed of the vehicle; it provides for neutralization of the alarm when the speed is below a given threshold, for example, 25 km/h. Determination of the energy due to unevennesses of the road makes it possible to introduce the second test of nontripping of the alarm, when that energy linked to the road exceeds a given

value. In this case, that corresponds to rolling over a very bad road and the energy due to the unevennesses of the road is such that it renders bearing detection too haphazard.

The safety inserts according to the invention can be made essentially of very rigid elastomeric material. They can also be made of any other material, such as a loaded or unloaded plastic.

The invention also concerns another device for the detection of bearing of a tire on its safety insert by reason of a pressure loss. Said device uses tire, rim and safety insert assemblies capable of triggering the emission of a vibrating signal when the tire comes in contact with the insert after a pressure loss in the tire. Such a device uses, for example, a generator 50 sensitive to the pressure emitting a predetermined radio signal when the bearing and the inner surface of the tire are in contact. Said generator 50 can be adhered to the inner surface of the tire, as in Figure 10b, or to the outer surface of an insert, as in Figure 10a.

The device comprises such a tire, rim and insert assembly and a single receiver of the signals emitted by the generators 50, as well as an indicator capable of warning the occupant of the vehicle of the bearing condition.
